

# A multiscale technique for finding slow manifolds of stiff mechanical systems

G. Ariel\*, J.M. Sanz-Serna†, R. Tsai‡

January 5, 2012

## Abstract

In the limit of infinite stiffness, the differential equations of motion of stiff mechanical systems become differential algebraic equations whose solutions stay in a constraint submanifold  $\widehat{\mathcal{P}}$  of the phase space. Even though solutions of the stiff differential equations are typically oscillatory with large frequency, there exists a slow manifold  $\widetilde{\mathcal{P}}$  consisting of non-oscillatory solutions;  $\widetilde{\mathcal{P}}$  has the same dimension as  $\widehat{\mathcal{P}}$  and converges to it as the stiffness approaches infinity. We introduce and analyze an iterative projection algorithm IPA that projects points in the phase space of a stiff mechanical system onto the associated slow manifold  $\widetilde{\mathcal{P}}$ . The algorithm is based on ideas (micro-integration, filtering) from the field of multiscale simulation and is applicable to initialize integration algorithms for both stiff ODEs and DAEs (including the initialization of Lagrange multipliers). The algorithm may also be combined with numerical integrators for both the stiff system and the limit constrained system.

Keywords: Slow manifolds, filtering, holonomic constraints

## 1 Introduction

In this paper we propose and analyze an iterative projection algorithm IPA for computing slow points of stiff mechanical systems, i.e. points that, when taken as initial data, do not give rise to rapidly oscillatory solutions. We also provide examples of several uses of that algorithm.

We are concerned with the stiff ordinary differential equations (ODEs)

$$\ddot{q} = F(q; t) - \omega^2 g'(q; t)^T g(q; t), \quad \omega \gg 1, \quad q \in \mathbb{R}^d, \quad g \in \mathbb{R}^k, \quad k \leq d. \quad (1)$$

and with the associated (index 3) differential algebraic equations (DAEs) [5], [14]

$$\ddot{q} = F(q; t) - g'(q; t)^T \lambda, \quad g(q) = 0. \quad (2)$$

A simple example is given by the DAEs that govern the motion of a planar pendulum and the ODEs that describe the mechanical system obtained by replacing the pendulum rod by a stiff spring (see Section 2.3).

In (1) and (2),  $F$  and  $g$  are smooth functions and, furthermore, it is assumed that for each  $q$  and  $t$  the  $k \times d$  Jacobian matrix  $g'(q; t)$  of  $g$  with respect to  $q$  has independent rows. In this way  $g(q; t) = 0$  defines a  $d - k$  time-dependent submanifold  $\widehat{\mathcal{C}} = \widehat{\mathcal{C}}(t)$  of  $\mathbb{R}^d$  and (2) describes a mechanical systems with forces  $F$  whose configuration is constrained to be in  $\widehat{\mathcal{C}}(t)$  at each time  $t$ . The equations in (2) include redundant, nonindependent configuration coordinates  $q$  and are sometimes called the Lagrangian equations of motion of the first kind of the mechanical system. The term  $-g'(q; t)^T \lambda$  represents the forces exerted by the constraints and  $\lambda \in \mathbb{R}^k$  is the vector of Lagrange multipliers. Throughout this paper, we denote the velocities by  $p = \dot{q}$ . If  $(\widehat{q}(t), \widehat{p}(t))$  is a solution of (2), from  $g(\widehat{q}(t); t) = 0$ , we may write

$$\dot{g}(\widehat{q}(t), \widehat{p}(t); t) = g'(\widehat{q}(t); t) \widehat{p}(t) + \frac{\partial g}{\partial t}(\widehat{q}(t); t) = 0,$$

so that, at each time  $t$ , the point  $(\widehat{q}(t), \widehat{p}(t))$  is on the time-dependent  $2(d - k)$ -dimensional submanifold  $\widehat{\mathcal{P}} = \widehat{\mathcal{P}}(t)$  of  $\mathbb{R}^d \times \mathbb{R}^d$  defined by the equations

$$g(q; t) = 0, \quad \dot{g}(q, p; t) = 0.$$

We shall say that  $\widehat{\mathcal{P}}$  is the *constraint* submanifold of the DAE (2).<sup>1</sup> In the important case where  $g$  does not depend on  $t$ , the equations of  $\widehat{\mathcal{P}}$  become  $g(q) = 0$ ,  $g'(q)p = 0$  and  $\widehat{\mathcal{P}}$  is the tangent bundle of the (time-independent) submanifold  $\widehat{\mathcal{C}}$  of  $\mathbb{R}^d$ . Of course the initial value given by (2) in tandem with  $q(t_0) = q_0$ ,  $p(t_0) = p_0$  only has a solution if the given initial point  $(q_0, p_0)$  is on  $\widehat{\mathcal{P}}(t_0)$ .

The motions of (1) are not constrained; the corresponding initial value problem is solvable for arbitrary  $(q_0, p_0)$  in the *phase space*  $\mathbb{R}^d \times \mathbb{R}^d$ . In (1),  $-\omega^2 g'(q; t)^T g(q; t)$  represents large  $\mathcal{O}(\omega^2)$  forces that are derived from the potential

$$V(q; t) = \frac{\omega^2}{2} g(q; t)^T g(q; t). \quad (3)$$

Those forces lie in the column space of  $g'(q; t)$ , i.e. they are orthogonal, in the *configuration space*  $\mathbb{R}^d$ , to  $\widehat{\mathcal{C}}$ . Their presence implies that, *typically*, solutions  $q(t)$  of (1) oscillate with large  $\mathcal{O}(\omega)$  frequencies in directions orthogonal to  $\widehat{\mathcal{C}}$ . However if  $g(q; t)$  is small, i.e. if  $q$  is not far away from  $\widehat{\mathcal{C}}$ , the force  $-\omega^2 g'(q; t)^T g(q; t)$  is of moderate

<sup>1</sup>Throughout the notation  $\widehat{\phantom{x}}$  will refer to entities related to the constraint manifold.

size and in fact it turns out (see Section 2) that there is a time-dependent  $2(d - k)$ -dimensional submanifold  $\tilde{\mathcal{P}} = \tilde{\mathcal{P}}(\omega; t)$  of  $\mathbb{R}^d \times \mathbb{R}^d$ ,  $\mathcal{O}(\omega^{-2})$  close to the constraint manifold  $\hat{\mathcal{P}}$  such that for  $(q_0, p_0)$  in  $\tilde{\mathcal{P}}(\omega; t_0)$  the solution of the initial value problem given by (1) and  $q(t_0) = q_0, p(t_0) = p_0$  has a *slow* solution, i.e. a solution that does not include rapidly oscillatory components. We say that  $\tilde{\mathcal{P}}$  is the *slow manifold* of (1).<sup>2</sup> This manifold is left invariant by (1): for solutions of (1),  $(q(t_0), p(t_0)) \in \tilde{\mathcal{P}}(\omega, t_0)$  at a given  $t_0$  implies  $(q(t), p(t)) \in \tilde{\mathcal{P}}(\omega, t)$  for each  $t$ .

It is well known [18], [13] that as  $\omega$  increases, the slow solutions of the stiff system (1) converge to solutions of the DAE (2). Moreover if, as  $\omega \rightarrow \infty$ , we consider fixed initial data  $(q_0, p_0)$  bounded away from the slow manifold, then the corresponding solutions  $(q(t), p(t))$  exhibit oscillations of increasing energy and therefore become unphysical. These are the arguments that allow the introduction of the constrained Lagrangian model (2) as the limit of unconstrained systems (2) of very large stiffness, see e.g. [4], Section 17. Slow manifolds are important in the analysis and numerical treatment of dynamical systems; a list of nearly one hundred references is given in the survey [19].

The present article is devoted to introducing and analyzing an algorithm that, for any given time  $t_0$  and point  $(q_0, p_0)$  in the phase space  $\mathbb{R}^d \times \mathbb{R}^d$ , finds the projection  $(\tilde{q}_0, \tilde{p}_0)$  of  $(q_0, p_0)$  onto the slow manifold  $\tilde{\mathcal{P}}(\omega; t_0)$ . The algorithm is based on the fact that the solution of (1) with initial condition  $(q_0, p_0)$  oscillates around the slow manifold. We integrate the corresponding stiff initial value problem in a small time window of  $\mathcal{O}(\omega^{-1})$  length to obtain a so-called micro-solution; the oscillations in the micro-solution are then filtered away by convolution with an averaging kernel and this results in a point  $(q_1, p_1)$  closer to the slow manifold than the initial  $(q_0, p_0)$ . The procedure is then *iterated* a few times to obtain a point sufficiently close to the slow manifold. An important feature of the algorithm is that the required work does not grow with the stiffness parameter  $\omega$ .

The ideas of micro-integration and filtering used here are borrowed from the field of multiscale methods for the integration of differential equations, see [11] and also [8], [9], [10], [12], [20], [1], [2], [3], [22], [6], [7]. In fact the iterative projection algorithm may be used to build *explicit* integrators to compute both slow solutions of (1) and solutions of (2) (see Section 6).

The paper is divided into seven Sections. Section 2 presents background material on slow solutions and slow manifolds, together with some examples that illustrate the relevant theory. The iterative algorithm IPA is introduced in Section 3. That section also reviews the process of filtering, with particular attention to the role of two parameters of the kernel that are crucial in the analysis: the number of vanishing moments and the number of continuous derivatives. The algorithm is analyzed in Section 4. Sections 5 and 6 are devoted to numerical experiments and Section 7 contains our conclusions.

All our results are trivially extended to cases where the left-hand sides of (1)–(2) are changed into  $M\ddot{q}$ , where  $M$  is a symmetric, positive definite mass matrix. The format  $-\omega^2 g'(q; t)^T g(q; t)$  may be replaced, as in [18] or [13], by a more general  $-\nabla V_\omega(q; t)$  with  $V_\omega$  a potential of size  $\mathcal{O}(\omega^2)$ , but the required treatment is somewhat more complicated than that presented here.

<sup>2</sup>Entities associated with the slow manifold will be identified by the notation  $\sim$ .

## 2 Slow solutions

This section contains some background material that is needed to present the iterative projection algorithm.

### 2.1 The slow manifold

We begin by defining the concept of *slow function* (see [15] Definition 2.1, [16] Definition 1.1). Let  $\omega > 0$  parameterize a family of vector-valued functions  $v$  of the variable  $t$ ,  $0 \leq t \leq T$ . Here the dependence of  $v$  on  $\omega$  is not incorporated to the notation for simplicity. We say that  $v$  is slow of order  $\ell = 0, 1, \dots$  if  $v$  has  $\ell$  continuous derivatives and there exist  $\omega_0 > 0$  such that

$$\sup_{\omega \geq \omega_0} \sup_{0 \leq t \leq T} \left| \frac{\partial^j v}{\partial t^j} \right| < \infty, \quad j = 0, \dots, \ell.$$

We say that  $v$  is *slow* if it is slow to any order  $\ell$ .

Let us review some relevant results from the literature. If  $(\hat{q}_0, \hat{p}_0)$  is a point on the constraint manifold  $\hat{\mathcal{P}}(t_0)$ , there exists ([18], Theorem 2.2) a point  $(\tilde{q}_0^\omega, \tilde{p}_0^\omega)$ ,  $\mathcal{O}(\omega^{-2})$  away from  $(\hat{q}_0, \hat{p}_0)$ , such that the solution of the initial value problem given by (1) and  $\tilde{q}(t_0) = \tilde{q}_0^\omega, \tilde{p}(t_0) = \tilde{p}_0^\omega$  exists in an  $\omega$ -independent time interval  $0 \leq t \leq T$  and is slow. The collection of all pairs  $(\tilde{q}_0^\omega, \tilde{p}_0^\omega)$  forms, for each  $t_0$  and  $\omega$ , a  $2(d-k)$ -submanifold  $\tilde{\mathcal{P}}(\omega; t_0)$  of  $\mathbb{R}^d \times \mathbb{R}^d$ . The time-dependent manifold  $\tilde{\mathcal{P}}(\omega; t)$  is invariant with respect to (1).

The dynamics of the solutions of (1) when the initial data  $(q_0, p_0)$  is in the neighborhood of  $\tilde{\mathcal{P}}(\omega; t_0)$  (but not on it) is studied carefully in [13] XIV.3 (see also Section 4 below). For the purposes of this paper it is crucial to note that those solutions oscillate around the slow manifold with frequencies proportional to  $\omega$ . Furthermore, these fast oscillations create in general a drift in the tangential direction; if  $\kappa$  measures the distance between the initial condition and the slow manifold, then the magnitude of the drift is  $\mathcal{O}(\kappa\omega^{-1} + \kappa^2)$ , see [15], Theorem 2.4.

Also of importance are the following remarks.

*Remark 1.* With the notation above, the solution  $(\tilde{q}(t), \tilde{p}(t))$  of the stiff ODE (1) with initial condition  $\tilde{q}(t_0) = \tilde{q}_0^\omega, \tilde{p}(t_0) = \tilde{p}_0^\omega$  and the solution  $(\hat{q}(t), \hat{p}(t))$  of the DAE (2) with initial condition  $\hat{q}(t_0) = \hat{q}_0, \hat{p}(t_0) = \hat{p}_0$  differ by  $\mathcal{O}(\omega^{-2})$ . However if (1) is solved with initial condition  $q(t_0) = \hat{q}_0, p(t_0) = \hat{p}_0$  the solution  $(q(t), p(t))$  does *not* differ from  $(\tilde{q}(t), \tilde{p}(t))$  by  $\mathcal{O}(\omega^{-2})$ . In fact while it is true that  $q(t) - \tilde{q}(t) = \mathcal{O}(\omega^{-2})$ , the estimation for the velocity is worse:  $p(t) - \tilde{p}(t) = \mathcal{O}(\omega^{-1})$ . This happens because a  $\mathcal{O}(\omega^{-2})$  change in the variable  $q$  implies a  $\mathcal{O}(\omega^{-2})$  changes in the oscillatory potential (3) and therefore  $\mathcal{O}(\omega^{-2})$  changes in kinetic energy or  $\mathcal{O}(\omega^{-1})$  changes in velocity.

*Remark 2.* Comparison of (1) and (2), together with the converge as  $\omega \rightarrow \infty$  of the slow solutions to the solution of the DAE clearly imply:

$$\lim_{\omega \rightarrow \infty} \omega^2 g(\tilde{q}(t); t) = \lambda. \quad (4)$$

The following examples illustrate these points.

## 2.2 A linear example

The scalar equation

$$\ddot{q} = -\omega^2(q - \cos t) \quad (5)$$

has the unique slow solution

$$\tilde{q} = A \cos t, \quad \tilde{p} = -A \sin t, \quad A = A(\omega) = \frac{\omega^2}{\omega^2 - 1}. \quad (6)$$

Since here the constraints<sup>3</sup> are

$$g = q - \cos t = 0, \quad \dot{g} = p + \sin t = 0,$$

the corresponding constrained problem (2) has the unique solution  $\hat{q}(t) = \cos t$ ,  $\hat{p}(t) = -\sin t$ . The fact that  $A = 1 + \mathcal{O}(\omega^{-2})$  implies that both  $\tilde{q}(t)$  and  $\tilde{p}(t)$  are  $\mathcal{O}(\omega^{-2})$  away from their constrained counterparts  $\hat{q}(t)$ ,  $\hat{p}(t)$ .

Consider now the initial value problem given by (5) together with the initial conditions  $(q(t_0), p(t_0)) = (q_0, p_0)$ . We write  $q_0 = A \cos t_0 + \rho_0$ ,  $p_0 = -A \sin t_0 + \sigma_0$ , so that  $\rho_0$  and  $\sigma_0$  measure the deviation from the ‘slow’ initial values  $\tilde{q}(t_0) = A \cos t_0$ ,  $\tilde{p}(t_0) = -A \sin t_0$ . The solution of the problem is given by

$$q(t) = A \cos t + \rho_0 \cos \omega(t - t_0) + \frac{\sigma_0}{\omega} \sin \omega(t - t_0), \quad (7)$$

$$p(t) = -A \sin t - \omega \rho_0 \sin \omega(t - t_0) + \sigma_0 \cos \omega(t - t_0); \quad (8)$$

it oscillates with the fast frequency  $\omega$  around the slow solution. It is important to point out the presence of the large factor  $\omega$  in (8) which implies that, if  $\rho_0$  and  $\sigma_0$  are  $\mathcal{O}(\omega^{-2})$ , the difference  $p(t) - \tilde{p}(t)$  will be  $\mathcal{O}(\omega^{-1})$  in agreement with Remark 1 above. In particular if  $(q_0, p_0)$  is taken on the constraint manifold, the velocity  $p(t)$  in (8) will be  $\mathcal{O}(\omega^{-1})$  away from  $\tilde{p}(t)$ .

Since we have  $\ddot{\hat{q}} = -\cos t$  and  $g' = 1$ , we conclude from (2) that the Lagrange multiplier is  $\lambda = \cos t$ . On the other hand, on the slow solution  $g = \tilde{q}(t) - \cos t = (A - 1) \cos t$ , and therefore (4) holds.

## 2.3 A nonlinear example

As a second example we study a strong spring in the plane. Consider a unit point mass with coordinates  $(x, y)$  moving in a plane. It is attached to one end of a stiff harmonic spring with unit length at rest and elastic constant  $\omega^2$ ; the other end of the spring is linked to a pivot fixed at the origin. If  $r = (x^2 + y^2)^{1/2}$ , the equations of motion

$$\begin{aligned} \ddot{x} &= -\omega^2(r - 1)\frac{x}{r}, \\ \ddot{y} &= -\omega^2(r - 1)\frac{y}{r}, \end{aligned}$$

---

<sup>3</sup>Here the constraint manifold  $\hat{\mathcal{P}}$  is reduced to a single (time-dependent) point.

provide a simple instance of (1) with  $d = 2$ ,  $q = (x, y)$ ,  $k = 1$ ,  $g = r - 1$ ,  $F \equiv 0$ . The corresponding DAE (2) reads

$$\begin{aligned}\ddot{x} &= -\lambda \frac{x}{r}, \\ \ddot{y} &= -\lambda \frac{y}{r}, \\ r &= 1.\end{aligned}$$

Clearly these equations govern the motion of a pendulum in the absence of gravity.

The problem is best analyzed after changing to polar coordinates, when the stiff ODE becomes

$$\ddot{r} = -\omega^2(r - 1) + r\dot{\phi}^2, \quad \frac{d}{dt}(r^2\dot{\phi}) = 0,$$

while the DAE is

$$\dot{r} = -\lambda + r\dot{\phi}^2, \quad \frac{d}{dt}(r^2\dot{\phi}) = 0, \quad r = 1.$$

The solution of the DAE is trivial: and  $r \equiv 1$  and  $\phi$  increases linearly with  $t$ . The Lagrange multiplier  $\lambda = \dot{\phi}^2$  does not change with  $t$  and represents the centripetal force exerted by the rod.

For the stiff ODE, the areal velocity  $M = (1/2)r^2\dot{\phi}$  is a constant of motion, and we may write

$$\ddot{r} = -\omega^2(r - 1) + \frac{4M^2}{r^3}, \quad (9)$$

so that  $r$  varies with  $t$  as the abscissa of a unit point mass under the effective potential

$$\frac{\omega^2}{2}(r - 1)^2 + \frac{2M^2}{r^2},$$

which possesses a minimum at the positive root  $r^* = r^*(M, \omega)$  of the equation

$$\omega^2 r^3(r - 1) = 4M^2.$$

This root obviously satisfies

$$r^* = 1 + \frac{4M^2}{\omega^2} + \mathcal{O}(\omega^{-4}).$$

If  $r(0) = r^*$  and  $\dot{r}(0) = 0$ , then  $r(t)$  and  $\dot{\phi}(t)$  remain constant (the tension in the spring exactly balances the centrifugal force so as to have a uniform circular motion). Thus, in this example, the slow two-dimensional manifold  $\tilde{P}$  in the phase space  $\mathbb{R}^4$  has the equations  $r = r^*$  and  $\dot{r} = 0$  and the constraint manifold  $\hat{P}$  is given by  $r = 1$ ,  $\dot{r} = 0$  (the tangent bundle to the unit circle); these manifolds are  $\mathcal{O}(\omega^{-2})$  away from each other because  $r^* = 1 + \mathcal{O}(\omega^{-2})$ . Note that, since  $r^*$  depends on  $M = (1/2)r^2\dot{\phi}$ , the relation  $r = r^*$  mixes coordinates and velocities and on its own does *not* define a one-dimensional manifold in the configuration plane  $\mathbb{R}^2$  of the variables  $(x, y)$  (i.e. the slow manifold is not the tangent bundle of a one-dimensional configuration manifold).

If the initial values  $r(0), \dot{r}(0)$  do not lie on  $\tilde{P}$ , the solution  $r(t)$  of (9) is not constant and undergoes fast oscillations *around the equilibrium*  $r^*$  in the effective potential well. Those fast oscillations are also present in the (tangential) variable  $\phi$  because  $M = (1/2)r^2\dot{\phi}$  remains constant at  $t$  varies.

The validity of Remarks 1 and 2 in this example is easily checked.

## 2.4 The bounded derivative principle

Kreiss's bounded derivative principle [15], [16] provides a means to identify the slow manifold. We illustrate this for the equation (5). From the differential equation we see that for  $\ddot{q}$  to be bounded independently of  $\omega$  (i.e. to have a solution slow to order 2), we must impose  $q = \cos t + \mathcal{O}(\omega^{-2})$ . Differentiating twice in (5) leads to

$$\frac{d^4}{dt^4}q = -\omega^2(\ddot{q} + \cos t) = \omega^4q - \omega^4 \cos t - \omega^2 \cos t,$$

and, accordingly, for solutions slow to order 4

$$q = \cos t + \frac{1}{\omega^2} \cos t + \mathcal{O}(\omega^{-4}).$$

The iteration of this procedure leads to (6). The slow manifold  $r = r^*, \dot{r} = 0$  of the pendulum may be found in exactly the same way.

## 3 Iterated projection algorithm IPA

In this section we describe the iterated projection algorithm IPA. This is based on the application of filtering kernels that we discuss immediately below.

### 3.1 Kernels

For our purposes a (filtering) kernel is an *even* real-valued function  $K(t)$  of the real variable  $t$ ,  $-\infty < t < \infty$ , supported in the interval  $[-1, 1]$ , and having unit mass:

$$\int_{-1}^1 K(t) dt = 1.$$

In order to filter at a time  $t_0$  a given vector-valued function  $v$  of the real variable  $t$  we compute the integral

$$v_{t_0}^* = \int_{-\infty}^{\infty} K_{\delta}(t)v(t+t_0) dt = \int_{-\delta}^{\delta} K_{\delta}(t)v(t+t_0) dt; \quad (10)$$

where  $K_{\delta}(t)$  is the scaling of  $K$  to the segment  $[-\delta, \delta]$ ,  $\delta > 0$ ,

$$K_{\delta}(t) = \delta^{-1}K(\delta^{-1}t).$$

The performance of a kernel depends on the values of two parameters  $\mu, \nu$ . The number  $\mu$  of *vanishing moments* of  $K$  is the largest integer such that

$$\int_{-1}^1 K(t)t^j dt = 0, \quad j = 1, \dots, \mu;$$

since  $K$  is an even function,  $K(t) \equiv K(-t)$ ,  $\mu$  is well defined and odd. If  $v$  is slowly varying and  $\delta \ll 1$ , then  $v_{t_0}^*$  is close to  $v(t_0)$  and the degree of closeness is governed by  $\mu$ :

**Lemma 1** *If  $v$  has a bounded  $(\mu + 1)$ -st derivative  $v^{(\mu+1)}$ , then*

$$\left| \int_{-\delta}^{\delta} K_{\delta}(t)v(t+t_0)dt - v(t_0) \right| \leq C \|v^{(\mu+1)}\|_{\infty} \delta^{\mu+1}, \quad (11)$$

for some constant  $C > 0$  that only depends on  $K$ .

On the other hand, if  $v$  oscillates rapidly around zero, then  $v_{t_0}^* \approx 0$  and the size of  $v_{t_0}^*$  is governed by the number  $\nu$  of continuous derivatives of  $K$ :

**Lemma 2** *Assume that  $v$  is  $\tau$ -periodic for some  $\tau > 0$ , continuous and with zero average (i.e.  $\int_0^{\tau} v(t) dt = 0$ ).*

1. *If  $K$  has  $\nu \geq 1$  continuous derivatives, then*

$$\left| \int_{-\delta}^{\delta} K_{\delta}(t)v(\omega(t+t_0)) dt \right| \leq C \|v\|_{\infty} \frac{1}{(\omega\delta)^{\nu}}, \quad (12)$$

where the constant  $C$  only depends on  $\tau, K$  and  $\nu$ .

2. *The same result holds true if  $K, K', \dots, K^{(\nu-2)}$  are continuous and  $K^{(\nu-1)}, K^{(\nu)}$  are continuous except perhaps at a number of points  $-1 = t_1 < t_2 < \dots < t_k = 1$  where they have jump discontinuities.*

The proofs of these lemmas are based on Taylor expansion of  $v$  and on integration by parts respectively (see [11] Lemma 2.2<sup>4</sup>). Note that we use the symbol  $C$  for a generic constant that may have different values at different occurrences.

The iterative projection algorithm filters solutions  $(q(t), p(t))$  of (1) that oscillate in a time-scale  $1/\omega$ ; this suggests to choose the filtering window size  $\delta$  as

$$\delta = L/\omega, \quad (13)$$

with  $L$  a large constant, so as to ensure that the right-hand side of (12) is small uniformly in  $\omega$ .

<sup>4</sup>Only item 1. of Lemma 2 is considered in [11] but the proof there works under the weaker hypothesis in item 2.

### 3.2 The algorithm IPA

Suppose that, at a fixed time  $t_0$ , we are given a point  $(q_0, p_0)$  which is close to the slow manifold  $\tilde{\mathcal{P}}$  and we wish to obtain a point  $(\tilde{q}, \tilde{p}) = \mathbb{P}(q_0, p_0)$  on  $\tilde{\mathcal{P}}$  and close to  $(q_0, p_0)$ . This algorithm is based on the observation that if we take  $(q_0, p_0)$  as an initial condition for (1) (i.e.  $(q(t_0), p(t_0)) = (q_0, p_0)$ ) the corresponding solution  $(q(t), p(t))$  (the so-called micro-solution) will consist of the superposition of a slow component and an oscillatory part. According to Lemmas 1 and 2, filtering the micro-solution will lead to a point  $(q_1, p_1)$  close to the value at  $t_0$  of the slow component, i.e. to a point close to the slow manifold. If  $(q_1, p_1)$  is not sufficiently close for the application in mind, the procedure may be iterated. In this way the algorithm IPA is as follows:

1. Initial data: Given  $\epsilon, L, t_0, (q_0, p_0)$ , set  $m = 0$ .
2. Micro integration: Solve the stiff problem (1) in the narrow time window  $t_0 - \delta \leq t \leq t_0 + \delta$ , with  $\delta$  chosen as in (13) and with initial condition  $(q(t_0), p(t_0)) = (q_m, p_m)$ . Denote by  $(q_m(t), p_m(t))$  the corresponding micro-solution.
3. Filtering: filter  $q_m(t)$  and  $p_m(t)$  with a kernel as in (10) to obtain  $q_{m,t_0}^*, p_{m,t_0}^*$ . Set  $q_{m+1} = q_{m,t_0}^*, p_{m+1} = p_{m,t_0}^*$ .
4. Stopping test: if

$$\max(|g(q_{m+1}, t_0) - g(q_m, t_0)|, |\dot{g}(q_{m+1}, p_{m+1}, t_0) - \dot{g}(q_m, p_m, t_0)|) \geq \epsilon \quad (14)$$

set  $m = m + 1$  and repeat steps 2. and 3. Otherwise set  $(\tilde{q}, \tilde{p}) = \mathbb{P}(q_0, p_0) = (q_{m+1}, p_{m+1})$  and stop.

In practice the micro-integrations have to be carried out numerically (see Section 5.2 below). The stopping criterion (14) will be discussed later.

## 4 Analysis

In this section we first analyze carefully the iterated projection algorithm as applied to two model problems that exhibit many—but not all—important features of the general situation. We then provide a less detailed study of the general case.

### 4.1 First model problem: damping of oscillations

We apply the iterated projection algorithm to the linear equation (5) at time  $t_0$  with  $q_0 = A \cos t_0 + \rho_0, p_0 = -A \sin t_0 + \sigma_0$  ( $\rho_0, \sigma_0$  quantify the deviation from the slow solution  $(A \cos t_0, -A \sin t_0)$ ). As we know, the micro-solution is given by (7)–(8).

Let us denote by  $\cos t_0 + c, \sin t_0 + s$ , and  $R$  the results of applying at time  $t_0$  the filtering procedure (10) to the functions  $\cos t, \sin t$ , and  $\cos \omega(t - t_0)$  respectively. Then filtering the micro-solution (7)–(8) leads to new values

$$q_1 = A \cos t_0 + \rho_1, \quad p_1 = -A \sin t_0 + \sigma_1,$$

with

$$\rho_1 = Ac + R\rho_0, \quad \sigma_1 = -As + R\sigma_0.$$

The old deviations  $\rho_0, \sigma_0$  are multiplied by the factor  $R$ . We have taken into account that, since we are assuming the kernel to be even, the output of filtering at  $t_0$  the function  $\sin(\omega(t - t_0))$  is 0. This fact is of particular significance because, as pointed out before,  $\sin \omega(t - t_0)$  appears in (8) multiplied by the large factor  $\omega$ .

After iterating the projection  $m$  times, we will have the relations

$$\begin{aligned} \rho_m &= \left(1 + R + \cdots + R^{m-1}\right)Ac + R^m \rho_0, \\ \sigma_m &= -\left(1 + R + \cdots + R^{m-1}\right)As + R^m \sigma_0, \end{aligned}$$

that provide the basis for the analysis that follows.

1. According to (12)–(13),  $|R| \leq C/L^\nu$ . It is then possible to choose  $L$  large enough to ensure that  $|R| < 1$ , which we assume hereafter. Then, as  $m \uparrow \infty$ , the errors  $\rho_m$  and  $\sigma_m$  will converge to

$$\rho_\infty = \frac{Ac}{1-R}, \quad \sigma_\infty = -\frac{As}{1-R}$$

and accordingly  $(q_m, p_m)$  will converge to a limit  $(q_\infty, p_\infty)$  close to the slow point

$$q_\infty = \tilde{q}(t_0) + \rho_\infty, \quad p_\infty = \tilde{p}(t_0) + \sigma_\infty.$$

2. The convergence factor  $|R|$  of the iteration is *independent* of  $\omega$ .
3. Due to the factor  $L^\nu$  in the bound  $|R| \leq C/L^\nu$ , kernels with a high number  $\nu$  of continuous derivatives allow for a faster decrease of the convergence factor  $|R|$  as  $L$  is increased.
4. From (11) and (13),

$$|c| \leq C \frac{L^{\mu+1}}{\omega^{\mu+1}}, \quad |s| \leq C \frac{L^{\mu+1}}{\omega^{\mu+1}} \quad (15)$$

and, correspondingly, item 1. above leads to the main estimate:

$$|q_\infty - \tilde{q}(0)| = \mathcal{O}(\omega^{-(\mu+1)}), \quad |p_\infty - \tilde{p}(0)| = \mathcal{O}(\omega^{-(\mu+1)}), \quad \omega \rightarrow \infty. \quad (16)$$

5. It should be observed that the error in  $q_\infty, p_\infty$  is determined by the error in *filtering the slow solution*.
6. The condition  $\mu > 1$  must hold if  $(q_\infty, p_\infty)$  is to provide a better approximation to  $(\tilde{q}(t_0), \tilde{p}(t_0))$  than the values  $(\hat{q}(t_0), \hat{p}(t_0))$  of the constrained solution that give an  $\mathcal{O}(\omega^{-2})$  error.
7. Since  $L$  has to be chosen large enough to ensure  $|R| < 1$ , the factor  $L^{\mu+1}$  in (15) will result in a large size of the error constants implied in (16). The algorithm will only be accurate if  $\omega$  is large with respect to  $L$ .

8. According to (14), the iteration is stopped when an integer  $\ell$  is found such that

$$|q_{\ell+1} - q_\ell| \leq \epsilon, \quad |p_{\ell+1} - p_\ell| \leq \epsilon. \quad (17)$$

It is easy to show that then

$$\ell \approx \frac{\log(1/\epsilon) + \log(|Ac| + |As| + |\rho_0| + |\sigma_0|)}{\log(1/|R|)} \quad (18)$$

and

$$|q_{\ell+1} - q_\infty| \leq \frac{R}{1-R}\epsilon, \quad |p_{\ell+1} - p_\infty| \leq \frac{R}{1-R}\epsilon. \quad (19)$$

Note that, since  $R$  is independent of  $\omega$ , these estimates are uniform in  $\omega$ .

## 4.2 Second model problem: tangential errors

Next we consider the uncoupled problem for  $q = (x, y) \in \mathbb{R}^2$  given by

$$\ddot{x} = F(x; t), \quad \ddot{y} = -\omega^2(y - \cos t).$$

Here ( $k = 1$ )

$$g = y - \cos t = 0, \quad \dot{g} = \dot{y} + \sin t = 0;$$

in configuration space  $\mathbb{R}^2$  the constraint manifold  $\widehat{\mathcal{C}}$  is a time-dependent straight line that moves parallel to the  $x$  axis. If  $(x_0, y_0, \dot{x}_0, \dot{y}_0)$  is the starting point for the algorithm at  $t = t_0$ , we would like the iterates  $(x_m, y_m, \dot{x}_m, \dot{y}_m)$  to move towards

$$(x_0, A \cos t_0, \dot{x}_0, -A \sin t_0)$$

as this is the point on  $\widetilde{\mathcal{P}}$  closest to  $(x_0, y_0, \dot{x}_0, \dot{y}_0)$ . We know from the preceding subsection that  $y_m, \dot{y}_m$  converge to the desired limits. The variable  $x$  is slow and filtering will change the initial  $x_0$  into  $x_1$  with  $|x_1 - x_0| \leq CL^{\mu+1}/\omega^{\mu+1}$  (see (11)), thus causing a small glide in configuration parallel to  $\widehat{\mathcal{C}}$ . At the next iteration  $x_2 - x_1 \approx x_1 - x_0$  because  $x_1$  is close to  $x_0$ , and therefore the glide from  $x_0$  will have approximately doubled. As more projections are carried out,  $x_m$  will move away linearly from  $x_0$  and, analogously,  $\dot{x}_m$  from  $\dot{x}_0$ . This is markedly different from the situation for the  $y$  component, where, as we saw, errors introduced at an iteration are subsequently dampened. In spite of these tangential displacements the algorithm will succeed because the iteration is stopped according to the criterion (14) i.e. when an integer  $\ell$  is found for which (see (17))

$$|y_{\ell+1} - y_\ell| \leq \epsilon, \quad |\dot{y}_{\ell+1} - \dot{y}_\ell| \leq \epsilon.$$

In fact we know that  $y_{\ell+1}, \dot{y}_{\ell+1}$  will be close to their target as in (19). Moreover, since the number of required iterations (18) is logarithmic in  $\epsilon$

$$|x_{\ell+1} - x_0| = \mathcal{O}(\log(1/\epsilon)\omega^{-(\mu+1)}), \quad |\dot{x}_{\ell+1} - \dot{x}_0| = \mathcal{O}(\log(1/\epsilon)\omega^{-(\mu+1)}).$$

Note that, except for a logarithmic factor, the overall error in the algorithm is governed by the errors in filtering the slow variables  $x$  and  $\dot{x}$  together with the errors in filtering the slow components of the  $y, \dot{y}$  variables. In other words the error is essentially independent of the distance of the initial  $(q_0, p_0)$  to the slow manifold  $\widetilde{\mathcal{P}}$ .

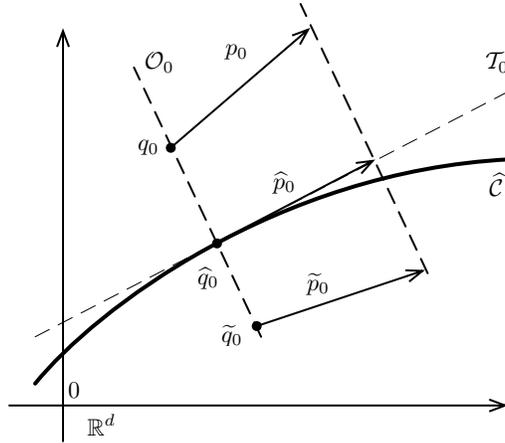

Figure 1: The diagram shows the space  $\mathbb{R}^d$  of the configuration variable  $q$ . In the DAE  $q$  is constrained to be on  $\hat{\mathcal{C}}$  and  $p$  is constrained to be in the tangent space  $\mathcal{T}_0$  at  $q$ . The point  $q_0 \in \mathbb{R}^d$  and the velocity vector  $p_0$  at  $q_0$  are projected onto the constraint manifold  $\hat{\mathcal{P}}$  to yield  $\hat{q}_0$  and  $\hat{p}_0$  and onto the slow manifold  $\tilde{\mathcal{P}}$  to yield  $\tilde{q}_0$  and  $\tilde{p}_0$

### 4.3 The general case

In the preceding model problem, the variables  $y$  and  $\dot{y}$  transversal to the constraints are not coupled to the tangential variables  $x, \dot{x}$ . In general, all variables will be coupled (as illustrated by the pendulum example of Section 2.3) and, in particular, there will be an influence of the fast vibrations onto the tangential dynamics. In order to investigate these issues, we now turn to the system (1) where, to simplify the exposition, we consider that  $F$  and  $g$  are independent of  $t$ . In this autonomous case we may also take  $t_0 = 0$ .

#### 4.3.1 Set-up

If the algorithm starting point  $(q_0, p_0)$  is close to the constraint manifold  $\hat{\mathcal{P}}$ , then its orthogonal projection  $(\hat{q}_0, \hat{p}_0)$  onto  $\hat{\mathcal{P}}$  is well defined (more precisely  $\hat{q}_0$  is the orthogonal projection in  $\mathbb{R}^d$  of  $q_0$  onto  $\hat{\mathcal{C}}$  and  $\hat{p}_0$  is the orthogonal projection of  $p_0$  onto the vector space  $\mathcal{T}_0$  tangent to  $\hat{\mathcal{C}}$  at  $\hat{q}_0$ ), see Fig. 1. Similarly, let  $(\tilde{q}_0, \tilde{p}_0)$  be the  $(\omega$ -dependent) point on the slow manifold  $\tilde{\mathcal{P}}$  whose orthogonal projection onto  $\hat{\mathcal{P}}$  coincides with  $(\hat{q}_0, \hat{p}_0)$ ; for  $\omega$  large,  $(\tilde{q}_0, \tilde{p}_0)$  is well defined and

$$|\tilde{q}_0 - \hat{q}_0| + |\tilde{p}_0 - \hat{p}_0| = \mathcal{O}(\omega^{-2}). \quad (20)$$

The next iterate  $(q_1, p_1)$  is obtained by filtering  $(q(t), p(t))$ ,  $|t| \leq L/\omega$ , the micro-solution starting from  $(q_0, p_0)$ , and our aim is to show that  $(q_1, p_1)$  is closer to  $(\tilde{q}_0, \tilde{p}_0)$  than  $(q_0, p_0)$ .

In a neighborhood of  $\widehat{q}_0$  in configuration space, we will decompose the dynamics of (1) into components orthogonal and tangent to  $\widehat{\mathcal{C}}$ . Let  $\mathcal{Q}_\perp$  and  $\mathcal{Q}_\parallel$  respectively denote full-rank  $k \times d$  and  $(d - k) \times d$  matrices such that the kernel of  $\mathcal{Q}_\perp$  is the vector space  $\mathcal{T}_0$  tangent to  $\widehat{\mathcal{C}}$  at  $\widehat{q}_0$ , the kernel of  $\mathcal{Q}_\parallel$  is the vector space  $\mathcal{O}_0$  orthogonal to  $\widehat{\mathcal{C}}$  at  $\widehat{q}_0$  and, for each  $v \in \mathbb{R}^d$ :

$$|v|^2 = |\mathcal{Q}_\perp v|_{\mathbb{R}^k}^2 + |\mathcal{Q}_\parallel v|_{\mathbb{R}^{d-k}}^2.$$

In particular  $\mathcal{Q}_\perp$  restricted to the  $k$ -dimensional subspace  $\mathcal{O}_0 \subset \mathbb{R}^d$  is an isometry onto  $\mathbb{R}^k$  and  $\mathcal{Q}_\parallel$  restricted to the  $(d - k)$ -dimensional subspace  $\mathcal{T}_0 \subset \mathbb{R}^d$  is an isometry onto  $\mathbb{R}^{d-k}$ . Furthermore the  $d \times d$  matrices  $\mathcal{Q}_\perp^T \mathcal{Q}_\perp$  and  $\mathcal{Q}_\parallel^T \mathcal{Q}_\parallel$  are the orthogonal projectors of  $\mathbb{R}^d$  onto  $\mathcal{O}_0$  and  $\mathcal{T}_0$  respectively.

The definitions of  $\widehat{q}_0$  and  $\widehat{p}_0$  imply

$$\mathcal{Q}_\parallel(q_0 - \widehat{q}_0) = 0, \quad \mathcal{Q}_\parallel(p_0 - \widehat{p}_0) = 0, \quad \mathcal{Q}_\perp \widehat{p}_0 = 0. \quad (21)$$

Let us denote by  $\kappa$  an upper bound for the orthogonal components of  $q_0 - \widehat{q}_0$  and  $p_0 - \widehat{p}_0$ :

$$|\mathcal{Q}_\perp(q_0 - \widehat{q}_0)| \leq \kappa, \quad |\mathcal{Q}_\perp(p_0 - \widehat{p}_0)| = |\mathcal{Q}_\perp p_0| \leq \kappa. \quad (22)$$

We have to assume that  $\kappa$  is small: in a nonlinear situation it is not expected that the algorithm will work if it starts from  $(q_0, p_0)$  far from the constraint manifold.<sup>5</sup> However, the applications presented later in the paper demand that no relation is assumed between  $\kappa$  and  $1/\omega$ ; these must be seen as independent small parameters. The behavior of the micro-solution  $(q(t), p(t))$  varies substantially with the size of  $\kappa$  relative to  $1/\omega$ . For instance, if  $\kappa \approx 1/\omega^2$ , then the energy in the transversal oscillations will be small and the dynamics of the micro-solution will be close to that of the slow solution. The case  $\kappa \approx 1/\omega$  treated in [13] corresponds to oscillatory energy that remains bounded as  $\omega \rightarrow \infty$ . On the other hand, larger values of  $\kappa$  will allow fast oscillations with larger amplitudes, which, in principle, may have a significant influence on the slow components of  $q, p$  and therefore impair the performance of the algorithm. In what follows we restrict the attention to the *worst* case where  $\kappa$  is large relatively to  $1/\omega$  (large oscillatory energy). In that scenario the distance from  $(q_0, p_0)$  to  $(\widehat{q}_0, \widehat{p}_0)$  (of order  $\kappa$ ) is much larger than the distance (see (20)) between  $(\widehat{q}_0, \widehat{p}_0)$  and  $(\widetilde{q}_0, \widetilde{p}_0)$ , so that we may consider that our aim is to show that  $(p_1, q_1)$  is closer to  $(\widehat{q}_0, \widehat{p}_0)$  than  $(q_0, p_0)$ .

After decomposing  $q(t) = \widehat{q}_0 + (q(t) - \widehat{q}_0)$  and observing that filtering is a linear process, it is clear that we have to show that the outputs of filtering the functions

$$y(t) = \mathcal{Q}_\perp(q(t) - \widehat{q}_0), \quad x(t) = \mathcal{Q}_\parallel(q(t) - \widehat{q}_0), \quad (23)$$

are sufficiently small, while the outputs of filtering the functions

$$\dot{y}(t) = \mathcal{Q}_\perp \dot{p}(t), \quad \dot{x}(t) = \mathcal{Q}_\parallel \dot{p}(t) \quad (24)$$

are close to  $\mathcal{Q}_\perp \widehat{p}_0 = 0$  (see (21)) and to  $\mathcal{Q}_\parallel \widehat{p}_0$  respectively.

<sup>5</sup>Note that if  $(q_0, p_0)$  is far from the constraint manifold the definition of  $(\widehat{q}_0, \widehat{p}_0)$  may not be possible.

### 4.3.2 Transversal oscillations

From (23) and (22), it follows that  $y(0) = \mathcal{O}(\kappa)$ . Similarly (24) and (22) lead to  $\dot{y}(0) = \mathcal{O}(\kappa)$ . From (1) the differential equation for  $y \in \mathbb{R}^k$  is:

$$\ddot{y} = \mathcal{Q}_\perp F(q) - \omega^2 \mathcal{Q}_\perp g'(q)^T g(q). \quad (25)$$

In the short micro-integration interval  $|t| \leq L/\omega$ , the value of  $q(t)$  will not deviate much<sup>6</sup> from its initial value  $q(0)$  and therefore we may replace  $g'(q)$  by the constant  $g'_0 = g'(\hat{q}_0)$ . We also note that

$$g(q(t)) = g(q(t)) - g(\hat{q}_0) \approx g'(\hat{q}_0)(q(t) - \hat{q}_0) = g'_0(q(t) - \hat{q}_0)$$

and, because  $g'_0$  is in  $\mathcal{O}_0$ ,

$$g'_0(q(t) - \hat{q}_0) = g'_0 \mathcal{Q}_\perp^T \mathcal{Q}_\perp (q(t) - \hat{q}_0) = g'_0 \mathcal{Q}_\perp^T y(t).$$

Finally,  $\mathcal{Q}_\perp F(q) = \mathcal{O}(1)$ , while the second term in the right-hand side of (25) is  $\mathcal{O}(\kappa\omega^2)$  and is therefore large relatively to  $\omega$  (recall we are studying the regime where  $\kappa\omega$  is large). In this way, going back to (25), we may write the approximation

$$\ddot{y} = -\omega^2 M_0 y, \quad M_0 = \mathcal{Q}_\perp g'_0{}^T g'_0 \mathcal{Q}_\perp^T,$$

with a relative error  $\mathcal{O}(\kappa)$  in the  $\mathcal{O}(\kappa\omega^2)$  right-hand side. The matrix  $M_0$  is symmetric and, since  $g'_0$  has full rank, it is also positive definite; therefore

$$y(t) = \cos(\omega\sqrt{M_0}t)y(0) + (\omega\sqrt{M_0})^{-1} \sin(\omega\sqrt{M_0}t)\dot{y}(0), \quad (26)$$

$$\dot{y}(t) = -\omega\sqrt{M_0} \sin(\omega\sqrt{M_0}t)y(0) + \cos(\omega\sqrt{M_0}t)\dot{y}(0). \quad (27)$$

These equations are very similar to (7)–(8) that were analyzed in detail. The variable  $y(t)$  undergoes linear oscillations with amplitude  $\mathcal{O}(\kappa)$  and frequencies  $\omega\lambda_i > 0$ , where  $\lambda_i^2$ ,  $i = 1, \dots, k$  are the eigenvalues of  $M_0$ . Thus the filtering procedure, after choosing the filtering interval length appropriately, will dampen  $y$  and produce a point  $(q_1, p_1)$  closer to  $\hat{\mathcal{P}}$  than the original  $(q_0, p_0)$ . Again the choice of an even filter is essential for dealing with the large first term in the right-hand side of (27).

Of course the analysis above may be then taken up from  $(q_1, p_1)$  in lieu of  $(q_0, p_0)$  with a correspondingly smaller value of the parameter  $\kappa$ .

### 4.3.3 Tangential dynamics

The initial conditions for the tangential part of the micro-solution are  $x(0) = 0 \in \mathbb{R}^{d-k}$  (see (21) and (23)) and  $\dot{x}(0) = \mathcal{Q}_\parallel p_0 = \mathcal{Q}_\parallel \hat{p}_0$  (see (21) and (24)). The projection of (1) onto  $\mathcal{T}_0$  leads to

$$\ddot{x} = \mathcal{Q}_\parallel F(q) - \omega^2 \mathcal{Q}_\parallel g'(q)^T g(q) \approx \mathcal{Q}_\parallel F(q) - \omega^2 \mathcal{Q}_\parallel g'(q)^T g'_0 \mathcal{Q}_\perp y(t).$$

<sup>6</sup>Roughly speaking  $x(t) - x(0) = \mathcal{O}(\omega^{-1})$  and  $y(t) - y(0) = \mathcal{O}(\kappa)$ . This may easily be rendered rigorous by a Gronwall argument.

The product  $\mathcal{Q}_{\parallel}g'(q)$  vanishes at  $q = \widehat{q}_0$  and, thus, the acceleration  $\ddot{x}$  will not attain values of magnitude  $\mathcal{O}(\kappa\omega^2)$  as  $\ddot{y}$  does. Freezing  $g'(q)^T$  at  $q = \widehat{q}_0$  as we did in (25) will not do now and we have to consider first-order terms:

$$g'(q(t))^T \approx g_0'^T + B_0(q(t) - \widehat{q}_0)$$

( $B_0$  is the corresponding Jacobian matrix). Moreover since  $\mathcal{Q}_{\parallel}(q(t) - \widehat{q}_0)$  is negligible with respect to  $\mathcal{Q}_{\perp}(q(t) - \widehat{q}_0)$ , we may replace  $(q(t) - \widehat{q}_0)$  by its projection onto  $\mathcal{O}_0$  and that would result in an equation

$$\ddot{x} = \mathcal{Q}_{\parallel}F(q) - \omega^2 C_0[y(t), y(t)],$$

for a suitable bilinear operator  $C_0$ , whose actual form is of no consequence. Finally, since  $\omega^2 C_0[y(t), y(t)] = \mathcal{O}(\kappa^2\omega^2)$  is large, we may disregard  $\mathcal{Q}_{\parallel}F(q)$  to obtain

$$\ddot{x} = \omega^2 C_0[y(t), y(t)], \quad (28)$$

an equation which shows, that in the regime under consideration, the tangential acceleration is mainly induced by the transversal fast oscillations. (This coupling is of course not present in simple cases where  $g'$  is constant and  $B_0 = 0$ .)

From (26), we know that  $y(t)$  is a combination of harmonic contributions with  $\mathcal{O}(\kappa)$  amplitudes and frequencies  $\omega\lambda_i$ ; then the right-hand side of (28) will be a combination of sine and cosine functions with amplitudes  $\mathcal{O}(\kappa^2)$  and frequencies  $\omega|\lambda_i \pm \lambda_j|$ . In particular the resonant combinations  $\omega|\lambda_i - \lambda_j| = 0$  will be present. In other words

$$\ddot{x} = \omega^2(\ell + D(t)),$$

where  $\ell$  is an  $\mathcal{O}(\kappa^2)$  constant vector and  $D(t)$  is oscillatory with Fourier modes with  $\mathcal{O}(\kappa^2)$  amplitudes and large frequencies proportional to  $\omega$ . Additionally, since in the right-hand side of (26) the first term is dominant, the function  $D(t)$  is even, except for an  $\mathcal{O}(\kappa^2/\omega)$  perturbation.

Integrating once we may write

$$\dot{x}(t) = \mathcal{Q}_{\parallel}\widehat{p}_0 + \omega^2 t\ell + \int_0^t \omega^2 D(s) ds.$$

Here the large  $\omega^2 t\ell$  term is annihilated by the (even) filter and the same is true for the dominant odd part of the integral. The even part of the integral is highly oscillatory with small  $\mathcal{O}(\kappa^2)$  amplitude (integration brings in a  $1/\omega$  factor); its contribution to  $p_1$  will also be  $\mathcal{O}(\kappa^2)$ , but with a smaller error constant by virtue of the dampening effected by the filter. Thus  $\mathcal{Q}_{\parallel}p_1$  will be  $\mathcal{O}(\kappa^2)$  away from  $\mathcal{Q}_{\parallel}\widehat{p}_0$ .

A new integration yields

$$x(t) = t\mathcal{Q}_{\parallel}\widehat{p}_0 + \omega^2 \frac{t^2}{2}\ell + \int_0^t ds \int_0^s \omega^2 D(u) du;$$

the iterated integral is oscillatory with small  $\mathcal{O}(\kappa^2)$  amplitude and  $t\mathcal{Q}_{\parallel}\widehat{p}_0$  will be destroyed by the filter. The quadratic term  $\omega^2(t^2/2)\ell$ ,  $|t| \leq L/\omega$  will at most produce a small  $\mathcal{O}(\kappa^2)$  contribution to  $q_1$ ; in fact for a kernel with  $\mu \geq 3$  vanishing moments that contribution will actually vanish. We conclude that  $\mathcal{Q}_{\parallel}(q_1 - \widehat{q}_0) = \mathcal{O}(\kappa^2)$ ; the tangential gliding of  $q_1$ ,  $p_1$  will be negligible relatively to the distance between the starting point and the slow manifold.

## 5 Numerical experiments: computing slow points

We now provide examples on the application of IPA. This section illustrates the direct application of the technique to find slow points and compute Lagrange multipliers. The next section explores possible combinations of the projection algorithm with ODE solvers.

### 5.1 A test problem

We use the test problem with  $d = 4$ ,  $q = (x_1, y_1, x_2, y_2)$  given by<sup>7</sup>

$$\begin{aligned}\ddot{x}_1 &= -\omega_1^2(r_1 - 1)\frac{x_1}{r_1} - \omega_2^2(r_{1,2} - 1)\frac{x_1 - x_2}{r_{1,2}}, \\ \ddot{y}_1 &= -\omega_1^2(r_1 - 1)\frac{y_1}{r_1} - \omega_2^2(r_{1,2} - 1)\frac{y_1 - y_2}{r_{1,2}}, \\ \ddot{x}_2 &= \phantom{-\omega_1^2(r_1 - 1)\frac{x_1}{r_1}} + \omega_2^2(r_{1,2} - 1)\frac{x_1 - x_2}{r_{1,2}}, \\ \ddot{y}_2 &= \phantom{-\omega_1^2(r_1 - 1)\frac{x_1}{r_1}} + \omega_2^2(r_{1,2} - 1)\frac{y_1 - y_2}{r_{1,2}},\end{aligned}$$

where

$$r_1 = (x_1^2 + y_1^2)^{1/2}, \quad r_{1,2} = ((x_1 - x_2)^2 + (y_1 - y_2)^2)^{1/2}.$$

For this system,  $k = 2$  and

$$g_1(q) = r_1 - 1, \quad g_2(q) = r_{1,2} - 1.$$

These differential equations govern the planar motion of two unit point masses; the first is joined to the origin through a stiff spring of elastic constant  $\omega_1^2 \gg 1$  and the second is joined to the first through a second stiff spring of elastic constant  $\omega_2^2 \gg 1$ . In the limit where  $\omega_1 \rightarrow \infty$ ,  $\omega_2 \rightarrow \infty$ , the springs become rigid rods of unit length and the system becomes a double pendulum with no gravity.

The experiments reported below have  $\omega_1 = \omega_2 = \omega$ ; simulations with  $\omega_1 = \omega$ ,  $\omega_2 = \alpha\omega$ , with  $\alpha$  a constant of moderate size, were also carried out, but do not provide additional insights. We also performed experiments where an external force of moderate size, such as gravity, was added to the model; again the corresponding results are very similar to those presented here.

### 5.2 Algorithmic details

All experiments in this paper use the piecewise cubic filter from [21]

$$K(t) = \begin{cases} 2 - 2|t| - 8|t|^2 + 8|t|^3, & 0 \leq |t| \leq 1/2, \\ 2 - \frac{22}{3}|t| + 8|t|^2 - \frac{8}{3}|t|^3, & 1/2 < |t| \leq 1. \end{cases}$$

---

<sup>7</sup>Note that now  $x$  and  $y$  represent cartesian coordinates in the plane and not tangential and transversal components as they did in the preceding section.

Table 1: Reduction of the constraint functions as the iterated projection proceeds from the starting point (29)–(30)

This has  $\mu = 3$  vanishing moments and satisfies the hypothesis in item 2. of Lemma 2 with  $\nu = 2$ . The parameter  $L$  that determines the filtering window (see (13)) is taken  $L = 6\pi$  in all experiments. Micro-integrations are performed by the standard Verlet algorithm with step-size  $h = (2\pi/\omega)/6$ ; since the micro-integration window has length proportional to  $1/\omega$  the number of steps in each micro-integration is independent of  $\omega$ . The tolerance  $\epsilon$  in the stopping criterion (14) is  $10^{-9}$  in the experiments with  $\omega = 1000$  or  $\omega = 10000$  and  $10^{-7}$  when  $\omega = 100$ .

### 5.3 Projecting onto the slow and constraint manifolds

We used the algorithm to project onto  $\tilde{\mathcal{P}}$  the point

$$x_1 = 1, \quad y_1 = 0.25, \quad x_2 = 2, \quad y_2 = 0, \quad (29)$$

$$\dot{x}_1 = 0, \quad \dot{y}_1 = -0.5, \quad \dot{x}_2 = 0, \quad \dot{y}_2 = 0.5, \quad (30)$$

when  $\omega = 1000$  and  $10000$ ; the choice of  $t_0$  is inconsequential as the problem is autonomous. For both values of  $\omega$  the algorithm takes five iterations to meet the required tolerance  $10^{-9}$ . Table 1 displays the evolution, as the iteration proceeds, of the values of the holonomic constraint functions  $g_1, g_2$  and the implied velocity constraints  $\dot{g}_1, \dot{g}_2$ . At the starting configuration in (29) the violation of the holonomic constraint is of the order of  $10^{-2}$ ; for  $\omega = 10000$  this implies an enormous  $\approx 10^5$  initial potential energy in the springs. We observe that in the first iteration the behavior of the algorithm is the same for both values of  $\omega$ . Away from the slow/constraint manifolds, the main effect of each iteration is the dampening the fast oscillations in the micro-solution and it was

shown in the preceding section that such dampening is uniform in  $\omega$ . For  $\omega = 1000$  the size of the components of  $g, \dot{g}$  converge to values  $\approx 10^{-6}$ . For  $\omega = 10000$  the limit values are 100 times smaller, in agreement with the fact that the slow manifold is  $\mathcal{O}(\omega^{-2})$  away from the constraint manifold  $g = \dot{g} = 0$ . As a side remark, let us comment that, in view of (4), the Table shows that the Lagrange multipliers associated with  $g_1$  and  $g_2$  have the values 1.01 and 0.895 respectively.

Note that the closeness between the slow and constraint manifold for  $\omega$  large opens the possibility for an alternative use of the algorithm: in order to find initial data  $(\hat{q}_0, \hat{p}_0)$  for the DAE (2) one may choose a very large value of  $\omega$  and project onto the slow manifold an initial guess  $(q_0, p_0)$ . Of importance here is the fact that the computational cost of the projection is independent of  $\omega$ .

As a second example we started from the point

$$\hat{x}_1 = 1, \quad \hat{y}_1 = 0, \quad \hat{x}_2 = 2, \quad \hat{y}_2 = 0, \quad (31)$$

$$\hat{\dot{x}}_1 = 0, \quad \hat{\dot{y}}_1 = -0.5, \quad \hat{\dot{x}}_2 = 0, \quad \hat{\dot{y}}_2 = 0.5, \quad (32)$$

that clearly satisfies the constraints  $g(q) = 0, g'(q)p = 0$  and therefore is not far away from the slow manifold. With  $\omega = 1000$  after two iterations the algorithm yields a point

$$\tilde{x}_1 \approx 1.00000150, \quad \tilde{y}_1 = 0, \quad \tilde{x}_2 \approx 2.00000275, \quad \tilde{y}_2 = 0, \quad (33)$$

$$\tilde{\dot{x}}_1 = 0, \quad \tilde{\dot{y}}_1 \approx -0.4999951, \quad \tilde{\dot{x}}_2 = 0, \quad \tilde{\dot{y}}_2 \approx 0.4999973. \quad (34)$$

Both springs have been stretched slightly as a consequence of the centrifugal effect of the nonzero tangential velocities. For  $\omega = 10000$ , two iterations are also required and the slow point given by the algorithm is

$$\tilde{x}_1 \approx 1.0000000150, \quad \tilde{y}_1 = 0, \quad (35)$$

$$\tilde{x}_2 \approx 2.0000000275, \quad \tilde{y}_2 = 0,$$

$$\tilde{\dot{x}}_1 = 0, \quad \tilde{\dot{y}}_1 \approx -0.499999952, \quad (36)$$

$$\tilde{\dot{x}}_2 = 0, \quad \tilde{\dot{y}}_2 \approx 0.499999973.$$

These results show once more the  $\mathcal{O}(\omega^{-2})$  distance between  $\hat{\mathcal{P}}$  and  $\tilde{\mathcal{P}}$ .

## 5.4 Computing Lagrange multipliers

Assume that it is required to integrate the DAE (2) with compatible initial data  $\hat{q}(t_0), \hat{p}(t_0)$ . At each step, the DAE solver will use an iteration to find the next values of  $q, p, \lambda$ . While at the very first step the initial data  $\hat{q}(t_0), \hat{p}(t_0)$  provide good starting guesses to initialize  $q$  and  $p$  in the iteration, it may be difficult to initialize the Lagrange multipliers for which no initial condition is available. After recalling (see (4)) that  $\lambda \approx \omega^2 g(\hat{q}(t_0))$ , we may apply the iterative projection algorithm to approximate  $\lambda$ . Here is an example. For the configuration in (33),  $g_1 = 1.49 \times 10^{-6}, g_2 = 1.23 \times 10^{-6}$ , and for the configuration in (35)  $g_1 = 1.50 \times 10^{-8}, g_2 = 1.25 \times 10^{-8}$ . We conclude

that the value of the Lagrange multipliers  $\lambda_1, \lambda_2$  at the point (31)–(32) have values  $\approx 1.50$  and  $\approx 1.25$  respectively. If the multipliers have to be determined with great accuracy it is of course possible to resort to a Richardson extrapolation with respect to  $\omega$ .

## 6 Numerical experiments: computing slow solutions

In this section we discuss several possibilities for numerically computing slow solutions  $(\tilde{q}(t), \tilde{p}(t))$ . As an example we use again the test problem of the preceding section. We shall compute the slow solution for  $0 \leq t \leq 10$  which coincides at  $t = 0$  with the slow point  $(\tilde{q}_0, \tilde{p}_0)$  obtained by projecting the initial point (31)–(32) onto  $\tilde{\mathcal{P}}$ . We shall report errors in the variables  $q$  and  $p$  at the final time  $t = 10$  measured in the Euclidean norm in  $\mathbb{R}^4$ ; of course here ‘error’ refers to the difference between the result provided by the particular algorithm being tested and the true  $\tilde{q}(10)$  or  $\tilde{p}(10)$  (these were found by the algorithm in Section 6.3 with `RelTol` =  $10^{-12}$ , `AbsTol` =  $10^{-14}$ ).

We emphasize that *the aim of this experiments is to test the iterative projection algorithm* and to illustrate the theory that underlies it; a full comparison between the efficiency of the different approaches is out of the scope of this contribution. For this reason we limit the methods tested to simple integrators like RATTLE, the classical fourth-order Runge-Kutta formula or the codes in the MATLAB suite. When comparing the results of the different approaches one should keep in mind the small dimensionality of the test problem and recall that, while the work in explicit ODE solvers grows linearly with the dimension  $d$  of the problem, DAE algorithms are necessarily implicit and may require an amount of work that grows like a higher power of  $d$  (the details vary with the implicit solver and with the sparsity of the problem).

### 6.1 Solving the DAE

It is clearly possible to obtain an approximation to  $(\tilde{q}(t), \tilde{p}(t))$  by solving numerically the associated DAE with initial condition  $(\hat{q}(0), \hat{p}(0))$ . We have implemented the well-known method RATTLE (see e.g. [17]), with the implicit equations solved by Newton iteration and the required Jacobian matrices computed analytically. The errors in approximating the slow solution are given in Fig. 2<sup>8</sup> where the step-sizes are  $H = 1/8, 1/16, \dots$  and  $\omega = 100, 1000, 10000$ . As we know, the difference between the exact DAE solution and the target  $(\tilde{q}(t), \tilde{p}(t))$  is  $\mathcal{O}(\omega^{-2})$  in both  $q$  and  $p$  and this explains the saturation of errors as  $H \rightarrow 0$ . As a consequence, for  $\omega = 100$  this method may only provide a very rough approximation to the solution sought. We note that this limitation will not disappear if RATTLE were replaced by a more accurate DAE solver.

<sup>8</sup>In order to render comparisons easier, the axes in this figure and those in the figures that follow share the same scaling.

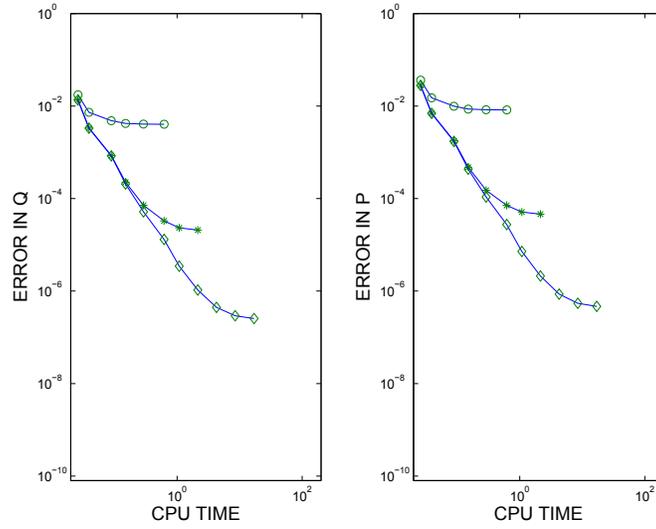

Figure 2: Errors for  $\omega = 100$  (circles),  $\omega = 1000$  (stars),  $\omega = 10000$  (diamonds) when the slow solution is approximated by numerical integration of the DAE

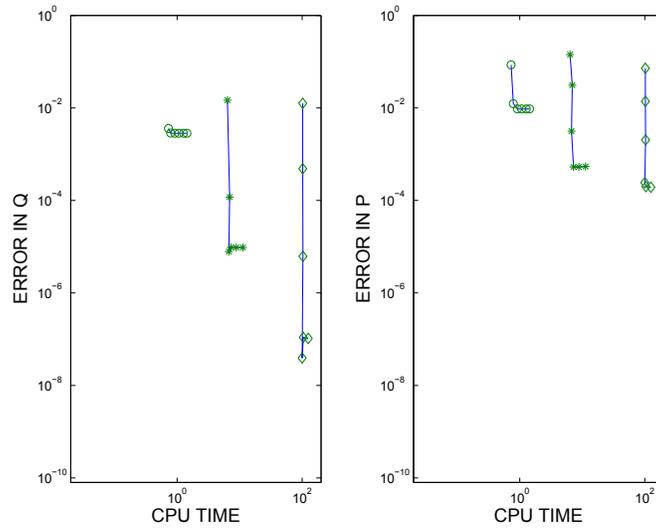

Figure 3: Errors for  $\omega = 100$  (circles),  $\omega = 1000$  (stars),  $\omega = 10000$  (diamonds) when the slow solution is approximated by numerical integration with `ode113` starting from the constraint manifold

## 6.2 Starting from the constraint manifold

Next we try to compute numerically  $(\tilde{q}(t), \tilde{p}(t))$  by solving the stiff ODE with the point (31)–(32) as an initial condition. This point is compatible with the constraints and accordingly  $\mathcal{O}(\omega^{-2})$  away from the correct initial data  $(\tilde{q}(0), \tilde{p}(0))$ . We performed this integration with *each* of the codes from the MATLAB suite, including the *implicit* solvers `ode15s`, `ode23s`, `ode23t`, `ode23tb`; the results reported correspond to the explicit high-order Adams code `ode113` as this turned out to be the most efficient. Six pairs of relative and absolute tolerances were tested:  $(\text{RelTol}, \text{AbsTol}) = (10^{-3}, 10^{-6})$ , (the default option);  $(10^{-4}, 10^{-7})$ ; ...;  $(10^{-8}, 10^{-11})$ . The results are given in Fig. 3. The code chooses very small step-sizes. Moving from  $\omega = 100$  to  $\omega = 1000$  multiplies the computational effort by 10; and the increase is even larger when going from  $\omega = 1000$  to  $\omega = 10000$ . With larger tolerances, the computational effort is virtually independent of  $(\text{RelTol}, \text{AbsTol})$ ; for those tolerances the choice of step-size is dictated by stability considerations and demanding additional accuracy does not require a substantial decrease in step-size with a high-order integrator. However for stringent tolerances, the code tries to follow accurately the small ripples that result from the starting point being close to the slow manifold  $\tilde{\mathcal{P}}$  but not on it. As we know from Remark 1 in Section 2.1, those ripples are of amplitude  $\mathcal{O}(\omega^{-2})$  in  $q$  and  $\mathcal{O}(\omega^{-1})$  in  $p$ . In that regime of stringent tolerances, a decrease in tolerance does imply an increase in computational effort. At the same time, in that regime, the reported errors saturate, because the `ode113` integration errors become negligible with respect to the difference between  $(\tilde{q}(t), \tilde{p}(t))$  and  $(\hat{q}(t), \hat{p}(t))$ . For  $\omega = 1000$  the saturation takes place at around  $10^{-5}$  in  $q$  and  $10^{-3}$  in  $p$ , for  $\omega = 10000$  at around  $10^{-7}$  and  $10^{-4}$  respectively. Clearly this technique is both more expensive and more inaccurate than that based on solving the DAE.

## 6.3 Projecting the initial condition onto the slow manifold

Next we integrated with each of the codes in the MATLAB suite the stiff ODE but using the iterative projection algorithm to identify the correct starting point  $(\tilde{q}(0), \tilde{p}(0))$ . Again the best performance corresponded to `ode113` whose results are presented in Fig. 4. Comparison with Fig. 3 shows that the iterative projection destroys the saturation of errors and it is now possible to obtain high accuracy. However the computational costs here are high and approximately coincide with those in Fig. 3: we are still solving the stiff equation and, even though the numerical solution starts on the slow manifold, the integration errors will force the solution to leave that manifold. We also note that the error in  $p$  are considerably larger than the errors in  $q$ .

We remark that also for the implicit codes `ode15s`, `ode23s`, `ode23tb` the computational load for a given tolerance is roughly the same whether the starting point is  $(\hat{q}(0), \hat{p}(0))$  or  $(\tilde{q}(0), \tilde{p}(0))$ . Only for `ode23t`, based on the trapezoidal rule, integrations from  $(\hat{q}(0), \hat{p}(0))$  are more expensive than integrations from  $(\tilde{q}(0), \tilde{p}(0))$  (the trapezoidal rule differs from the other implicit methods tested in that it is not strictly stable at infinity).

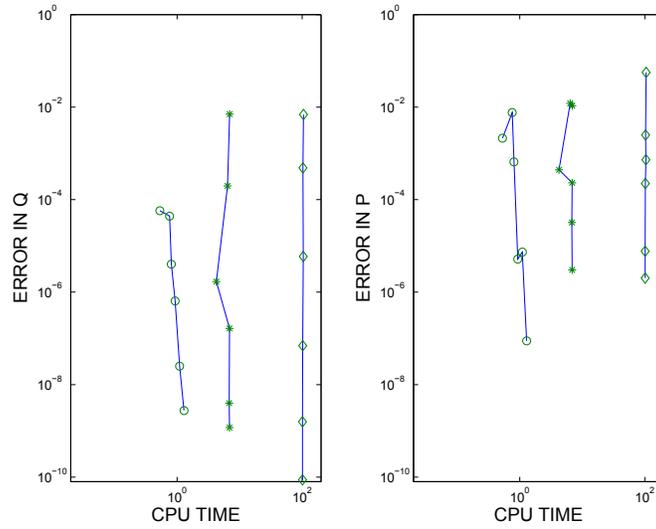

Figure 4: Errors for  $\omega = 100$  (circles),  $\omega = 1000$  (stars),  $\omega = 10000$  (diamonds) when the slow solution is approximated by numerical integration with `ode113` starting from the slow manifold

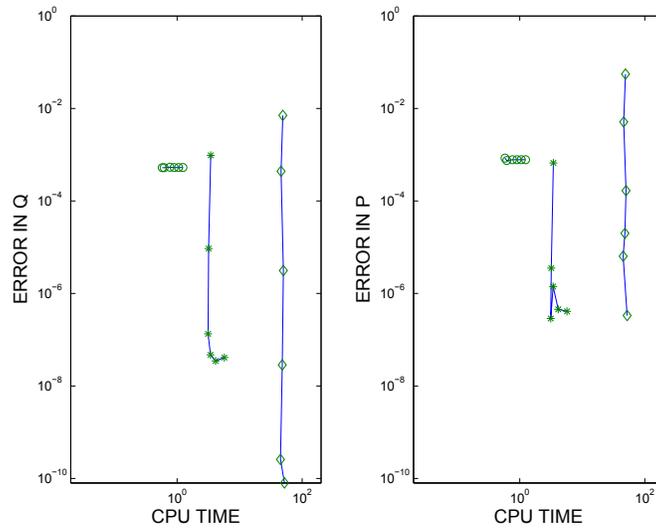

Figure 5: Errors for  $\omega = 100$  (circles),  $\omega = 1000$  (stars),  $\omega = 10000$  (diamonds) when the slow solution is approximated by numerical integration with `ode113` starting from the slow manifold and projected back at  $t = 1, 2, \dots, 9$

## 6.4 Projecting periodically onto the slow manifold

As in the preceding subsection, the integration starts from  $(\tilde{q}(0), \tilde{p}(0))$  and the results reported correspond to `ode113`. At times  $t = 1, 2, \dots, 9$ , the integration is halted and the numerical solution projected onto the slow manifold  $\tilde{\mathcal{P}}$ ; the integration is then taken up from the projected point. (Note that, in order not to give this technique an unfair advantage, we do not project at the final time where errors are measured.) The results may be seen in Fig. 5. For  $\omega = 1000$  and  $\omega = 10000$  this technique is a clear improvement on that of the preceding subsection: the errors are smaller and the computational cost lower because the solution is not allowed to move too far away from the slow manifold. For  $\omega = 100$  the errors are independent of the tolerance as the error of integrating with `ode113` is dominated by the  $\mathcal{O}(\omega^{-4})$  errors of the projections at  $t = 2, 3, \dots$ . In this connection we also observe that for  $\omega = 1000$  the errors saturate at  $\approx 5 \times 10^{-8}$  in  $q$  and  $5 \times 10^{-7}$  in  $p$ , again due to the presence of the projection errors.

It is clear that the projection may be applied more or less frequently than at  $t = 1, 2, \dots$ , perhaps monitoring the growth in the constraint functions  $q(q), g'(q)p$  as the integration proceeds. Rather than attempting to tune the frequency of the projections, we explore in the next subsection the possibility of projecting at each function evaluation of the integrator so as to only pick information from the slow manifold.

## 6.5 Projection onto the slow manifold at each function evaluation

To be definite we shall illustrate the technique by means of the classical fourth-order Runge-Kutta (RK4) scheme, but it may be combined with any other integrator.

The system being solved is written in first order format  $\dot{z} = \phi(z)$ ,  $z = (q, p)$ ; given the approximation  $z_n$  at the beginning of a step, RK4 evaluates  $\phi$  at four stage vectors

$$\begin{aligned} Z^1 &= z_n, \\ Z^2 &= z_n + \frac{H}{2}\phi(Z^1), \\ Z^3 &= z_n + \frac{H}{2}\phi(Z^2), \\ Z^4 &= z_n + H\phi(Z^3). \end{aligned}$$

and then sets

$$z_{n+1} = z_n + \frac{H}{6}(\phi(Z^1) + 2\phi(Z^2) + 2\phi(Z^3) + \phi(Z^4)). \quad (37)$$

We change the computation of the evaluation points into (as before,  $\mathbb{P}$  stands for iterative projection):

$$\begin{aligned} Z^1 &= \mathbb{P}z_n, \\ Z^2 &= \mathbb{P}\left(z_n + \frac{H}{2}\phi(Z^1)\right), \\ Z^3 &= \mathbb{P}\left(z_n + \frac{H}{2}\phi(Z^2)\right), \\ Z^4 &= \mathbb{P}\left(z_n + H\phi(Z^3)\right) \end{aligned}$$

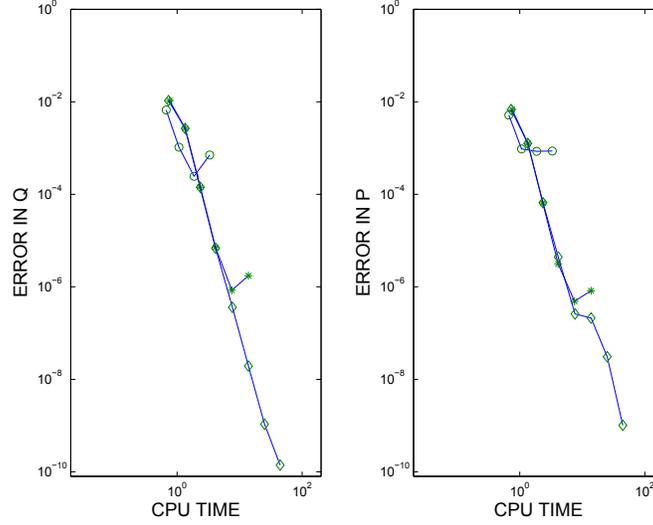

Figure 6: Errors for  $\omega = 100$  (circles),  $\omega = 1000$  (stars),  $\omega = 10000$  (diamonds) when the slow solution is approximated by numerical integration with the classical RK4 with projection before each function evaluation

and replace (37) by

$$z_{n+1} = \mathbb{P}z_n + \frac{H}{6}(\phi(Z^1) + 2\phi(Z^2) + 2\phi(Z^3) + \phi(Z^4)). \quad (38)$$

Thus we only evaluate  $\phi$  at points on the slow manifold. The modification requires to use  $\mathbb{P}$  four times per time step.

Results are reported in Fig. 6 for step-sizes  $H = 1/2, 1/4, \dots$ . We first note that, as distinct from the other experiments based on integrating the stiff ODE, the integration now works satisfactorily with large step-lengths commensurate with the slowly varying character of the target solution. However the savings afforded by the large values of the step-length are partly offset by the fact that each time step of the RK4 algorithm is very expensive due to the need to iterate the projection at each of the four stages. We also observe that now the errors in the  $q$  and  $p$  variables share the same behavior, as it was the case when integrating the DAE but not in the other experiments based on integrating the stiff ODE.

For  $\omega = 10000$  the errors in the algorithm are mainly due to the RK4 integrator and follow an  $\mathcal{O}(H^4)$  pattern. In fact the slopes in the figure are slightly higher than that associated with an order four method due to the fact that halving  $H$  less than doubles the computational effort because the average number of iterations of the projection algorithm at each stage decreases slightly. For  $H = 1/2, \dots, 1/16$  the behavior of the method with  $\omega = 1000$  and  $\omega = 10000$  is essentially the same; work and accuracy are  $\omega$ -independent. However with  $\omega = 1000$  and  $H = 1/32$  and  $H = 1/64$  the  $\mathcal{O}(\omega^{-4})$  projection errors become important; when  $H$  is small halving the step-length leads to

an increase in error as more projections are performed. For  $\omega = 100$  the computational cost for fixed  $H$  is slightly smaller than for  $\omega = 1000$  or  $10000$ , thus reflecting that we used a less demanding tolerance to stop the iteration.

The RK4 integration provides a hard test for the accuracy of the iterative projection algorithm. For instance, at each time step, the point  $Z^{2*} = z_n + (H/2)\phi(Z^1)$  to be projected is  $\mathcal{O}(H^2)$  (uniformly in  $\omega$ ) away from the slow manifold; in view of the factor  $\omega^2$  in the oscillatory potential (3) this implies an oscillatory energy that grows unboundedly as  $\omega$  increases. Several iterations (typical 3–5) are required to meet the stopping criterion (14) when projecting  $Z^{2*}$  to find  $Z^2$ . The analysis in Section 4.3.3 predicts that those iterations introduce an  $\mathcal{O}(H^4)$  tangential error in the projected  $Z^2$ ; this error changes  $z_{n+1}$  by an  $\mathcal{O}(H^5)$  amount, compatible with the overall algorithm being fourth order accurate.

Comparing all the results reported above, it appears that *for the problem at hand* and  $\omega = 10000$  the DAE solver is the best option if high accuracy is not necessary; if it is, the projected RK4 is the most efficient choice. For such a large value of  $\omega$  the difference between the slow solution and the constrained solution is very small and one may interpret the RK4 algorithm as a method to solve the DAE without solving implicit equations. Note in this connection that since the computational effort is independent of  $\omega$  it is possible to increase further the stiffness in order that the slow solutions provide a better approximation to the solutions of the DAE.

## 7 Conclusions and future work

We have introduced and analyzed an algorithm that projects points in the phase space of a stiff mechanical system onto the associated slow manifold. The algorithm is based on ideas (micro-integration, filtering) from the field of multiscale simulation and is applicable to initializing integration algorithms for both stiff ODEs and DAEs (including the initialization of Lagrange multipliers).

We have shown that by applying the proposed iterated projection algorithm, conventional numerical integrators may enjoy the benefits of improved accuracy and reduced computational cost. Future work is needed both to identify the integrators that are best suited for this approach and to construct optimal filters.

By performing the iterated projection before each function evaluation, it is possible to integrate DAEs with ODE solvers. While this approach—that does not require to solve implicit equations—is unlikely to be as efficient as standard DAE solvers for small problems, its application to large problems is worth considering.
